LOW-SPEED WIND-TUNNEL MEASUREMENTS OF THE LIFT, DRAG AND PITCHING  
MOMENT ON THREE SYMMETRICAL OGEE-WING MODELS AND ON A  
SYMMETRICAL SLENDER WING-BODY MODEL

---

SUMMARY

Measurements have been made of the lift, drag and pitching moment of three ogee models and a wing-body model, all having a slenderness ratio (semispan/root chord) of 0.209. The associated surface flow patterns were also observed.

Although the models were symmetrical and did not represent strictly comparable fully optimised designs of possible layouts for a supersonic transport, some useful low-speed aerodynamic comparisons between the integrated or ogee models and the wing-body model were obtained. The results show:-

- (i) very similar lift characteristics,
- (ii) a slightly smaller drag for the wing body model,
- (iii) better static longitudinal stability characteristics for the wing-body model, especially when the wing planform was not faired smoothly into the body.

Attempts to improve the longitudinal stability of one of the ogee wings, by minor planform modifications at the rear of the wing intended to reduce the forward movement of aerodynamic centre with incidence, were largely unsuccessful, but provided some useful data on the effect of trailing-edge shape. For the wing-body model, drooping the nose was a successful modification and it is suggested that a drooped nose version of the wing-body model (without any planform fillet) would have good static longitudinal stability.

## 1 INTRODUCTION

This Note gives the results of 4 ft x 3 ft low-speed tunnel tests made as part of a general experimental investigation of the characteristics of various layouts for supersonic transport aircraft intended to cruise at Mach numbers in the region of 2.0. These layouts have included some configurations where the body is completely integrated with the wing and the resulting planform is ogee in shape, and others where the combination of a wing and body is more easily identifiable. The investigations reported here were concerned with the flow properties and the static longitudinal characteristics of four symmetrical models, namely three wings with ogee planforms and integrated bodies and one wing-body combination.

For all four models the slenderness ratio  $s/c_0$  was 0.209 while the planform area ratio  $p (= S/bc_0)$  was 0.430, 0.450 and 0.467 for the ogee wings, and 0.455 for the wing-body combination. Allied studies of the effects of lengthwise and spanwise camber on the longitudinal characteristics of the  $p = 0.450$  ogee planform are reported elsewhere<sup>1</sup>.

In addition to the measurements on the four basic models, some attempts to alleviate the forward movement of aerodynamic centre with increase of lift were made on the  $p = 0.430$  ogee wing and on the wing-body combination. The nature of these modifications is described in section 2 and the results discussed in section 3.3. A simplified wing-body model was also tested to find the contributions of the body and the planform fillets to the stability of the complete model, and an analysis of these tests is presented in section 3.4.

Studies of the flow over and around these models were made using surface flow and smoke techniques to see if the changes in sweep-back along the leading-edge and/or the presence of a body destroyed the unified flow originally aimed at in these slender shapes. The results of these observations are discussed in section 3.1.

## 2 DETAILS OF MODELS AND TESTS

The main dimensions of all the models are given in Table 1. The  $p = 0.430$  ogee planform was taken from a project study by Hawker Siddeley Aviation, whilst the other two (with  $p = 0.450$  and  $0.467$ ) were designed by Dr. J. Weber of R.A.E. to give more gradual changes of sweep-back along the leading-edge (Fig.1). The cross sections of all three models were simplified versions of the firms proposed "integrated" layout (Table 1 and Fig.1).

The wing-body model ( $p = 0.455$ ) was made to a planform and sections obtained from an early Bristol Aircraft design by shearing the cambered sections of that design to give a symmetrical model. The planform of the wing blended via a fillet into a narrow strake on each side of the body (Figs.2 and 3). A further model ( $p = 0.450$ ) was made with a detachable body and without fillets or strakes in order to investigate their effects\*. The planform of this model

---

\* Since one model had fillets and strakes and the other had neither, the terms "with fillet" and "without fillet" will be used in referring to these models in the test and figures.

is compared with that of the  $p = 0.450$  ogee in Fig.3. All the models were made of wood.

Measurements of the lift, drag and pitching moment of the models were made in the 4 ft x 3 ft low-speed tunnel during 1960, using the normal wire rig and overhead balance. Most of the tests were made at a tunnel speed of 200 ft/sec, but, because of model vibration, for the ogee models at incidence above  $20^\circ$  the speed was reduced to 100 ft/sec. The incidence range was from  $-4^\circ$  to  $26^\circ$ . The Reynolds based on the overall model lengths and a speed of 200 ft/sec ranged between 2.6 and  $2.9 \times 10^6$ . Except for a few surface flow tests, the transition was left free.

Since the tests showed a forward movement of aerodynamic centre with increase of lift, methods of alleviating this mild "pitch-up" were sought. For the ogee models, the effect of providing extra non-linear lift at the rear was investigated by attaching brass plates to the lower surface of the  $p = 0.430$  model to extend the planform; six shapes were tried (Table 2 and Fig.4(a)). On the wing-body model, a decrease in the lift on the forebody was attempted, both by simple linear droop at the nose and by a parabolic droop (Table 2 and Fig.4(b)).

Visualization of the flow over the upper surface of all the models was obtained using lampblack suspended in paraffin<sup>2</sup> at tunnel speeds of up to 180 ft/sec. Some extra observations of the flow above the wing-body models were made at 10 ft/sec using liquid titanium tetrachloride which fumes in moist air. The models were transferred from the wire rig to a rear sting mounting for both these flow tests.

The results of all the balance measurements are presented in Tables 3-7 and discussed in section 3. The tunnel constraint corrections applied to the balance measurements include the effect of model length calculated by the method of Ref.3. Since breakdown of the leading-edge vortices did not occur for the range of incidence tested, there was only a small wake blockage correction.

### 3 RESULTS AND DISCUSSION

#### 3.1 Flow visualization

From very low incidences the surface flow patterns on the ogee wings showed the presence of the leading-edge vortices which dominate the flow over slender wings with sharp edges. These vortices were continuous for all the models over the whole range of incidence covered; differences between the wings being limited to variations in the positions of the primary vortex. The spanwise location of this vortex can be conveniently specified by using the point of inflexion in the flow lines which are produced in the upper surface flow patterns. Fig.19 shows such patterns for the three ogee wings at an incidence of  $15^\circ$ . At this incidence, at 50% root chord the spanwise positions of the primary vortex were as follows:-

$p$	0.430	0.450	0.467
$y/s'$	0.42	0.53	0.55

whilst for all three wings the secondary separation occurred at  $y/s' \approx 0.7$ .

At lower incidences, up to about  $5^\circ$ , there were some signs of further flow separations inboard of the primary vortex attachment lines on the forward part of the wings. However, these were considered to be an effect of the low Reynolds number of the tests and were eliminated when a transition wire was fixed round the nose.

For the complete wing-body model the flow was more complex. At  $5^\circ$  of incidence the flow was still attached on the body with the wing leading-edge separation starting in the wing fillet region at about 30% of the body length. Separation of the flow from the upper surface of the body started just below  $10^\circ$  of incidence and by  $\alpha = 15^\circ$  was clearly marked (Fig.20), resulting in the formation of body vortices which trailed back down the centre of the model. The separation from the wing leading-edge started a little nearer the nose at the higher incidences but, because the strakes on the side of the body were small and not very sharp, the separation over the range of incidence tested never began ahead of about 25% of the body length. As incidence was increased and the wing vortices grow in strength and moved inboard, they pulled the body vortices down towards the model, so that, following the onset of body asymmetry at  $\alpha \approx 20^\circ$ , the body vortices wrapped in succession around the port wing vortex (Fig.20). This was clearly demonstrated by the smoke tests.

Similar results were obtained on the model without a fillet. In this configuration, the length of the body overhang was greater and at full-scale the onset of body-vortex asymmetry at zero sideslip might be expected to occur at a lower incidence than that for the layout with fillet. Some of the effects of vortex asymmetry, and the limitations of the small-scale 4 ft x 3 ft tunnel models in assessing the incidence at which asymmetry commences, are discussed in Ref.4.

A noticeable feature of these flow tests made on a sting rig was the steadiness of the wing-body models compared with the ogee models. These latter were so unsteady at the higher incidences that the tunnel speed had to be reduced to 60 ft/sec. Similar problems were experienced with the ogee models in the force tests; and furthermore, some comparative measurements of damping in yaw on a  $p = 0.450$  ogee model and a wing-body model have shown that the ogee alone experienced negative damping in yaw at high incidence<sup>4</sup>.

### 3.2 Lift, drag and pitching moments of the basic shapes

The lift, drag and pitching moment coefficients of the four models are given in Tables 3 and 5. These coefficients have been calculated using the areas and aerodynamic mean chords of the whole planform in each case. Lift curves are plotted in Fig.5 for the three ogee wings and in Fig.9 for the complete wing-body model. The lift coefficients for all these models, all having the same slenderness ratio are very similar, though Fig.5 shows a slight tendency for lift at a given incidence to decrease with increasing value of  $p$ . At  $15^\circ$  of incidence, the four models have lift coefficients some 6% higher than those from the mean curve drawn in Ref.5 for gothics ( $p = 0.667$ ) and deltas ( $p = 0.5$ ). These latter were flat plate models and Ref.5 shows that taking into account thickness would widen the differences in lift between the present shapes and the pure gothics and deltas. Further systematic work on the effect of planform and thickness on lift is clearly desirable. This is partially being covered by tests at present in progress on a series of wings specially designed to investigate more systematically the effect of planform on aerodynamic centre position.

The lift-dependent drag factor and the lift/drag ratio plotted in Fig.6 for the ogee models (transition free) show little effect on the approach drag within the range of  $p$  tested, the difference in lift-dependent drag factor arising mainly from the change in aspect ratio, i.e.  $K/A$  is nearly constant. Fig.10 shows some advantage for the wing-body model.

The pitching moments plotted in Fig.7 for the ogees, and in Fig.11 for the wing-body configuration with and without fillets, show the vital importance of careful choice of planform as regards the static longitudinal stability.

### 3.3 Aerodynamic centre position and attempts to improve the static longitudinal stability

For most of the expected subsonic range of lift coefficient 0.1 to 0.7\*, the positions of the aerodynamic centre moves forward with increasing lift coefficient (Fig.13). This forward movement is most marked for the ogee wings, particularly in the  $C_L$  range 0.1 to 0.5. In Fig.14 the pitching moment coefficients for the three ogee models and the wing-body model with and without fillets have been replotted about moment centres chosen to give neutral static longitudinal stability at  $C_L = 0.5$ . It is evident that for the three ogee wings tested the amount of elevator needed to trim at low speed and the amount of camber needed to trim at high speed will be greater than that needed for the wing-body layout, assuming similar rearward movements of aerodynamic centre with Mach number, and no centre of gravity change through the speed range.

Attempts to reduce the rate of forward movement of the aerodynamic centre with lift coefficient were made for both ogee and wing-body layouts. Thus, for the ogee model  $p = 0.430$ , six different shapes of extension to the rear of the planform were made, to see if more non-linear lift could be obtained aft of the moment centre by adding to the area beneath the leading-edge vortices (Fig.4(a)). An analysis of the results given in Table 4 and plotted in Fig.8 shows the following changes in static stability margin ( $\Delta h_n$ ) between  $C_L = 0.1$  and 0.7 as compared with the basic wing.  $\Delta h_n$  is given as a fraction of the centre-line chord  $c_o$  which is the same for all seven configurations.

Basic wing	Wing with extension					
	A	B	C	D	E	F
0.039	0.050	0.044	0.049	0.051	0.038	0.022

Only the large rectangular extension F yields any reduction in the rate of forward movement of the aerodynamic centre.

On the wing-body model the effect of reducing the non-linear lift at the front was tried, the forebody being drooped to reduce the local angle of incidence. Such nose droop is desirable for pilot's view in the approach and

\* Assuming an approach lift coefficient in the neighbourhood of 0.5 airworthiness requirements will demand that the aircraft be adequately cleared to  $C_L \approx 0.7$ .

to delay the onset of body vortex asymmetry<sup>4</sup>. Results with simple droop angles of 10° and 20°, as well as with a parabolic droop, are plotted in Figs.9 and 12. For these models the changes in the static-stability margin  $\Delta h/c_o$  between  $C_L = 0.1$  and 0.7 are listed below.

Basic model	Model cut for droop tests	10° droop	20° droop	Parabolic arc droop
0.015	0.014	0.009	0.008	0.006

The gains due to droop are not large, but are sufficient to ensure that the wing-body layout even with a fillet does have a nearly linear pitching moment v lift relationship.

For both integrated and wing-body layouts the forward movement of the aerodynamic centre with increase of lift will be greater when camber is applied to the wing, but there is some evidence that for cambers producing the same pitching moment increment this change is smaller for the wing-body than the integrated layout<sup>6</sup>.

The positions of the aerodynamic centre at a lift coefficient of 0.5 for all the models tested are shown in Fig.15, plotted against the position of the centroid of area of their total planforms. The figure also shows the mean line taken from Ref.7 for thick wings. Analysis of the results with trailing-edge extensions to the  $p = 0.430$  ogee model shows that if the length from the apex of the wing to the centre of the trailing-edge of the extension is used as the reference length in defining the positions of the aerodynamic centre and centroid of area then the aerodynamic centre position of all the variants A-F correlate well with the basic wing position along a line parallel to the line taken from Ref.7.

### 3.4 Contribution of the body and fillet to the lift and pitching moment of the wing-body model

In Figs.16 and 17 the lift and pitching moment coefficients of the two wing-body models based on the area of the wing alone are plotted together with the results for the wing alone. The effect of the body and fillet on the overall lift of the wing is very small and the lift curve using the new reference area, i.e. that of a mild gothic wing is identical with that taken from Ref.5. A chordwise redistribution of lift is indicated by Figs.16 and 17. This is shown most clearly by the position of the centre of pressure (Fig.18), and although the addition of the body to the wing gave a more constant centre of pressure position through the range of incidence, the subsequent addition of the fillet caused a rapid forward movement of the centre of pressure at the higher incidences. The effect of this latter addition on the aerodynamic centre position is shown in Fig.13.

Since the size of the strakes on the complete model was insufficient to fix the beginning of the leading-edge separation at one point for all incidences, while, with the mid-wing position the wing vortices failed to

collect the body vortices at the lower incidences and to prevent them trailing over the fin position, it is considered that fillets of this type serve no useful purpose.

#### 4. CONCLUSIONS

The tests show the effect of a limited range of planform shape variation on the low-speed static longitudinal stability of slender supersonic transports and enable some low-speed aerodynamic comparisons to be made between the integrated and wing-body layouts.

For the three ogee planforms tested, the changes in leading-edge sweep were gradual enough not to impair continuous vortex development along the leading edge. With the wing-body arrangement, flow separations from the body at moderate incidence gave rise to body vortices which trailed back down the centre of the model. At high incidences these body vortices became asymmetric and wrapped round the wing leading-edge vortices. The presence of a planform fillet in the wing-body junction, continued forward as small strakes on the side of the body, yielded no improvements and introduced uncertainty in the position of the start of the wing leading-edge vortices. Further work on other wing-body arrangements not reported here has demonstrated the variations in wing and body vortex interaction which can be obtained as the relative strengths and positions are changed.

All the models tested had the same slenderness ratio and showed virtually no change in lift coefficient, based on the total planform area, within the small range of  $p$  tested. These lift coefficients were some 6% higher than those measured earlier for gothic and delta wings of the same slenderness ratio but, assessing the lift coefficient of the wing-body models on the area of the basic wing gave the same lift as measured on the wing alone and on the gothic and delta wings.

Analysis of the pitching moments showed a forward movement of aerodynamic centre with increase of lift on all the models, this being more pronounced for the ogee planforms. Adding wing root planform fillets to the wing-body model increased the forward movement of aerodynamic centre. Attempts to reduce this movement on one of the ogee models by trailing-edge extensions were not very successful. However, on the complete wing-body model drooping the forebody yielded some benefit, and this improvement taken in conjunction with the effect of the fillet indicates that a drooped nose version of the wing-body model without a fillet should be virtually free from forward movement of the aerodynamic centre with incidence.

95	23.43	0.40	-	10.09	10.11	10.17
100	24.67	0.15	-	10.29	10.29	10.29

All the transverse sections were formed by drawing tangents from the wing edges to the arcs given by the centre radius. The planform of the p = 0.430 wing was taken from a project study by Hawker Siddeley Aviation Ltd and the others defined by the relationships

$$s(x) = 1.2x - 2.4x^2 + 2.2x^3 + 3x^4 - 3x^5$$

for p = 0.450

and

$$s(x) = 1.4x - 5.3x^2 + 12.4x^3 - 9.5x^4 + 2x^5$$

for p = 0.467

The leading edge radius was of the order of 0.01 in.

100.00	27.75	0	11.575	11.575	11.575	0.02

The above dimensions refer to the 27.75 in. long model. The planform and cross sections for this model were taken from a Bristol Aircraft Ltd design. The dimensions of the 27 in. long model were scaled from the above table. The leading edge radius was of the order of 0.01 in.

TABLE 2

Details of trailing-edge extensions to ogee model,  $p = 0.430$

Extension	Extra length in inches	% of wing span extended	% increase of area	$\frac{C_{L_{max}}}{C_{L_{max}}}$ with extensions / $C_{L_{max}}^{basic}$
A	0.91	100	4.29	0.999
B	1.37	100	8.80	1.000
C	0.92	66 $\frac{2}{3}$ span	2.88	0.991

\* Note  $C_D$  was reduced by 0.0004 in determining L/D for the  $p = 0.450$  ogee because the  $C_{D_0}$  for this wing was 0.0080 compared with 0.0076 for the two others.

LOW-SPEED WIND-TUNNEL MEASUREMENTS OF THE LIFT, DRAG AND PITCHING MOMENT ON THREE SYMMETRICAL OGEE-WING MODELS AND ON A SYMMETRICAL SLENDER WING-BODY MODEL.  
Kirby, D.A. November 1963.

Measurements have been made of the lift, drag and pitching moment of three ogee models and a wing-body model, all having a slenderness ratio (semispan/root chord) of 0.209. The associated surface flow patterns were also observed.

Although the models were symmetrical and did not represent strictly comparable fully optimised designs of possible layouts for a supersonic transport, some useful low-speed aerodynamic comparisons between the integrated or ogee models and the wing-body were obtained. The results show:-

LOW-SPEED WIND-TUNNEL MEASUREMENTS OF THE LIFT, DRAG AND PITCHING MOMENT ON THREE SYMMETRICAL OGEE-WING MODELS AND ON A SYMMETRICAL SLENDER WING-BODY MODEL.  
Kirby, D.A. November 1963.

Measurements have been made of the lift, drag and pitching moment of three ogee models and a wing-body model, all having a slenderness ratio (semispan/root chord) of 0.209. The associated surface flow patterns were also observed.

Although the models were symmetrical and did not represent strictly comparable fully optimised designs of possible layouts for a supersonic transport, some useful low-speed aerodynamic comparisons between the integrated or ogee models and the wing-body were obtained. The results show:-

(Over)

- (i) very similar lift characteristics,
- (ii) a slightly smaller drag for the wing-body model,

(iii) better static longitudinal stability characteristics for the wing-body model, especially when the wing planform was not faired smoothly into the body.

Attempts to improve the longitudinal stability of one of the ogee wings, by minor planform modifications at the rear of the wing intended to reduce the forward movement of aerodynamic centre with incidence, were largely unsuccessful, but provided some useful data on the effect of trailing-edge shape. For the wing-body model, drooping the nose was a successful modification and it is suggested that a drooped nose version of the wing-body model (without any planform fillet) would have good static longitudinal stability.

- (i) very similar lift characteristics,
- (ii) a slightly smaller drag for the wing-body model,

(iii) better static longitudinal stability characteristics for the wing-body model, especially when the wing planform was not faired smoothly into the body.
