EXPERIMENTAL DROPLET IMPINGEMENT ON SEVERAL TWO-DIMENSIONAL  
AIRFOILS WITH THICKNESS RATIOS OF 6 TO 16 PERCENT

By Thomas F. Gelder, William H. Smyers, Jr., and Uwe von Glahn

SUMMARY

The rate and area of cloud droplet impingement on several two-dimensional swept and unswept airfoils were obtained experimentally in the NACA Lewis icing tunnel with a dye-tracer technique. Airfoil thickness ratios of 6 to 16 percent, angles of attack from  $0^{\circ}$  to  $12^{\circ}$ , and chord sizes from 13 to 96 inches were included in the study. The data were obtained at 152 knots and are extended to other conditions by dimensionless impingement parameters.

In general, the data show that the total and local collection efficiencies and impingement limits are primary functions of the modified inertia parameter (in which airspeed, droplet size, and body size are the most significant variables) and the airfoil thickness ratio. Local collection efficiencies and impingement limits also depend on angle of attack. Secondary factors affecting impingement characteristics are airfoil shape, camber, and sweep angle. The impingement characteristics obtained experimentally for the airfoils were within  $\pm 10$  percent on the average of the characteristics calculated from theoretical trajectories. Over the range of conditions studied, the experimental data demonstrate that a specific method can be used to predict the impingement characteristics of swept airfoils with large aspect ratios from the data for unswept airfoils of the same series.

INTRODUCTION

Knowledge of the local and total rates of cloud droplet impingement and of the surfacewise extent or limit of droplet impingement on bodies is required for the design and evaluation of icing-protection equipment for aircraft. These impingement characteristics are important factors in determining the extent of the surface to be protected, the shape and location of some ice formations on aircraft components, the aerodynamic penalties associated with icing of aircraft surfaces, and the local and total requirements for various thermal and fluid protection systems.

Previous studies (refs. 1 to 12) report the droplet trajectories about several two-dimensional bodies and bodies of revolution. These studies used differential analyzers for computing the droplet paths after the flow field about the body had been obtained. An empirical method for obtaining the impingement characteristics of airfoil sections is presented in reference 13. This method, however, is more suited to airfoils with blunt leading edges, because the basic data used in developing the method were obtained from four Joukowski airfoils and only one low-drag airfoil. For the two-dimensional case, a method for applying trajectory data from unswept airfoils to swept airfoils is presented in reference 14.

Droplet trajectories about bodies with unknown or complex flow fields are difficult to obtain with a differential analyzer. Therefore, a wind-tunnel method using a dye-tracer technique to obtain experimentally the impingement characteristics of bodies has been developed (ref. 15). In this technique water treated with known small quantities of a water-soluble dye is sprayed into the tunnel airstream by nozzles a large distance ahead of the body. The surface of the body is covered with blotter paper or a similar absorbent material upon which the dyed droplets impinge and are absorbed essentially upon contact. At the point of droplet impact and absorption, a permanent dye trace is deposited. The amount of dye deposited in a measured time interval can be determined by a colorimetric analysis of the blotter paper and can be converted into the amount of impinged water that produced the dye trace. From such an analysis and from known values of spray-cloud water content and droplet sizes, the impingement characteristics of a body can be determined readily, as discussed in reference 15.

In an extensive program of icing studies conducted in the NACA Lewis icing tunnel on various two- and three-dimensional bodies, experimental impingement data on six swept and two unswept airfoils (all two-dimensional) have been obtained. Although the airfoils used in these studies were a rather ad hoc collection of shapes and sizes, this report makes these data generally available and correlates the data as much as possible. The impingement data were obtained with airfoil chord sizes ranging from 13 to 96 inches, three volume-median droplet sizes ranging from 11 to 19 microns in diameter, and a nominal airspeed of 152 knots. The thickness ratio of the airfoils studied varied from 6 to 16 percent.

The airfoil impingement rates and limits obtained are presented in terms of dimensionless impingement parameters. These dimensionless parameters allow interpolation and extension of the experimental results over a wide range of operating conditions. The experimental impingement values for several airfoils are compared with values calculated from theoretically obtained trajectory data.

3689

APPARATUS

Airfoil Models

This study of droplet impingement on various airfoil sections was conducted in the 6- by 9-foot test section of the NACA Lewis icing tunnel. The models, unless otherwise noted, were made of wood and spanned the 6-foot height of the tunnel (fig. 1). The airfoils are listed in the following table, and dimensionless streamwise sections are presented in figure 2.

Airfoil section (fig. 2)	Chord length in streamwise direction, in.	Remarks
(a) Joukowski 0015	13	
(b) Joukowski 0015	96	Smooth sheet-metal surface
(c) 63 <sub>2</sub> -015	13	
(d) 65 <sub>2</sub> -015	13	
(e) 65 <sub>2</sub> -216	96	<sup>1</sup> Sheet-metal surface modified by 3/16-in.-thick de-icing boot extending from $s_u$ of 0.156 to $s_l$ of 0.250 (ref. 16)
(f) 65 <sub>1</sub> -212	13	
(g) 65 <sub>1</sub> -212	72	
(h) 65 <sub>1</sub> -206	72	Although the low-drag range for this series airfoil is $<0.1$ for thickness ratios $<0.12$ and thus the subscript 1 is usually omitted, it is retained herein to preserve similarity with the 65 <sub>1</sub> -212 section
(i) 65 <sub>1</sub> -212	87.9	Swept 35°, design section in plane perpendicular to leading edge
(j) 65 <sub>1</sub> -206	87.9	

<sup>1</sup>Symbols are defined in appendix A.

The leading edge of the models was about 1.5 and 2.2 chord lengths from the entrance of the test section for the 96- and 72-inch-chord airfoils, respectively, and 9 chord lengths for the 13-inch-chord airfoils. These longitudinal locations indicate the length of the upstream flow field.

UL-1 DRUCK

The local pressures on the surface of several models were obtained by use of pressure belts. These experimental data, uncorrected for tunnel wall effects, were used to indicate variations from the theoretical pressure distributions.

### Spray System and Related Equipment

The spray cloud was provided by air-water atomizing nozzles located in the quieting chamber upstream of the tunnel test section. The nozzles were always positioned to provide a cloud that was relatively uniform in liquid-water content and droplet-size distribution in the test section. The dye-water solution and air pressures to the nozzles were set by means of pressure transmitters and manometers. The spray was turned on and off by fast-action solenoid valves, while the spray duration was set and recorded by an electric timer. Further details of the spray system are described in reference 15.

### PROCEDURE

#### Blotter Mounting

For the larger models, a 3-inch-wide blotter was rubber-cemented to a vellum strip, which in turn was cemented to the airfoil surface as shown in figure 1. The cementing prevented the blotter from being lifted from the airfoil surface by aerodynamic forces. The edges of the blotter were also taped to the airfoil surface. The vellum strip prevented damage to the blotter during removal from the model. After exposure to the spray cloud the vellum and blotter were removed as a unit and later separated carefully. For the small models a 2-inch-wide blotter was stretched tightly over the leading edge and taped to the airfoil surface along all the blotter edges.

#### Tunnel Conditioning and Blotter Exposure

In order to minimize the evaporation of the droplets during their time of travel from the spray nozzles to the body (about  $3/4$  sec), the entire tunnel airstream was nearly saturated before the body was exposed to the dyed-water spray. Saturation of the test-section airstream was achieved through the control of tunnel air temperature and the addition of steam into the tunnel until a light condensation cloud resulted.

The studies reported herein were conducted at the following nominal conditions: Free-stream velocity, 152 knots; static pressure, 28.1 inches of mercury; and static air temperature, 50° F.

3689

The procedure for each run was to preload the air and dyed-water pressure in the spray system and preset the exposure time. (Air-water gage pressure ratios similar to those used in ref. 15 - i.e., 0.5, 0.6, and 0.8 - were used herein to obtain impingement data; low pressure ratio was used to obtain large droplet sizes, while high pressure ratio was used to obtain small droplets.) With the tunnel air properly conditioned as to speed, temperature, and humidity, the blotter-wrapped model was exposed to the dyed spray for the preset time interval. After tunnel shut-down, the blotter was removed from the model.

In these studies the exposure time varied from 2 to 7 seconds for the 13-inch-chord airfoils and from 3 to 12 seconds for the large-chord airfoils at air-water pressure ratios of 0.5 to 0.8, respectively.

For each air-water pressure ratio, a relatively uniform cloud with local liquid-water-content variations within  $\pm 10$  percent and essentially the same droplet-size distribution were obtained. The reproducibility of the average liquid-water content from one model exposure to the next was about  $\pm 5$  percent.

#### Spray Cloud Properties

The cloud total liquid-water content was obtained by collecting dye from the spray cloud in an aspirating device (a tube that draws in air and liquid water at free-stream conditions, ref. 15). The inlet velocity of the device was always within 1 percent of the free-stream value, denoting theoretically a 100-percent collection efficiency.

The droplet-size distribution was determined by the method outlined in reference 15, in which the experimental impingement rates for cylinders are related to theoretical data for similar cylinders. In the present study, however, small 36.5-percent-thick Joukowski airfoils were used instead of cylinders. The absolute values of droplet size from this airfoil section (see appendix B) generally confirm those obtained from the cylinders of reference 15, but the body size trend is reduced from that of reference 15.

The ratio of droplet diameter to volume-median diameter<sup>1</sup> is presented in figure 3 as a function of the ratio of cumulative liquid-water content to total liquid-water content. The volume-median droplet diameters are believed accurate within  $\pm 6$  percent. These data are from the aspirator and 36.5-percent Joukowski airfoil analyses for the three spray conditions (air-water pressure ratios) studied.

---

<sup>1</sup>Volume-median droplet diameter is that diameter for which half the total liquid-water content is contained in droplets larger than the volume median and half in droplets smaller than the volume median.

The pertinent spray cloud properties are summarized in the following table:

Air-water pressure ratio	Air pressure, lb/sq in. gage	Water (dye solution) pressure, lb/sq in. gage	Approx. max. droplet diam., $d_{max}$ , microns	Range of total liquid-water content, $W_t$ , g/cu m	Volume-median droplet diam., $d_{med}$ , microns
0.5	60	120	59	0.46-0.65	18.6
.6	60	100	48	.37- .50	16.7
.8	80	100	29	.22- .33	11.5

3689

The number and spacing of the spray nozzles varied during the course of the airfoil program because of other unrelated test programs interspersed between those reported herein. These changes resulted in a range of cloud liquid-water content, as noted in the previous table, and were accounted for in analyzing the experimental impingement data. Droplet-size distribution was not affected by these nozzle changes.

#### Colorimetric Analysis

In the colorimetric analysis of the dyed blotter, small ( $\frac{1}{8} \times \frac{1}{2}$ -in. or  $\frac{1}{16} \times 1$ -in.) segments of area  $\Delta A_s$  are punched from the blotter as shown in figure 4. The dye is dissolved out of each segment with a known quantity of distilled water (ref. 15). The concentration of this solution is determined by the amount of light of a suitable wavelength transmitted through the solution in a calibrated colorimeter. The amount of dye collected on the segment is converted into the weight of water (dye-water solution) that impinged on the blotter segment during the exposure. The local impingement rate  $\bar{W}_\beta$  for a segment as given in reference 15 is expressed as

$$\bar{W}_\beta = \frac{0.794 \text{ Pb}}{t \Delta A_s}, \frac{\text{lb water}}{(\text{hr})(\text{sq ft})} \quad (1)$$

#### ANALYSIS OF DATA

The analysis of the data obtained from the dye-impingement records consists in evaluating the local and total collection efficiencies of the airfoils and the extent or limit of impingement on the airfoil surfaces. In order to analyze the experimental data, the water content and

droplet-size distribution of the spray cloud also must be known. Finally, methods of extending the data for conditions other than those used in the tests must be employed in order to render the data generally useful. A detailed discussion of the dye analysis is presented in reference 15 and reviewed herein for convenience in presenting the experimental data.

The local rate of water-droplet impingement  $\bar{W}_\beta$  and limit of impingement  $s_{\max}$  are obtained as a direct result of the dye-tracer technique used herein. The dimensionless impingement parameters  $\bar{\beta}$  and  $\bar{E}_m$  are obtained from the following equations (ref. 15):

$$\bar{\beta} = \frac{\bar{W}_\beta}{0.329 U_0 w_t} \quad (2)$$

$$\bar{E}_m = \frac{\int_{s_{l,\max}}^{s_{u,\max}} \bar{W}_\beta dA_s}{0.329 U_0 w_t A_F} = \frac{1}{A_F} \int_{s_{l,\max}}^{s_{u,\max}} \bar{\beta} dA_s \quad (3)$$

For a two-dimensional airfoil, equation (3) is rewritten for convenience as

$$\bar{E}_m = \frac{\int_{s_{l,\max}}^{s_{u,\max}} \bar{W}_\beta ds}{0.329 U_0 w_t h} = \frac{1}{h} \int_{s_{l,\max}}^{s_{u,\max}} \bar{\beta} ds \quad (4)$$

Equation (4) is based on projected frontal height  $h$  rather than on the airfoil thickness ratio used by some investigators. Figure 5 shows ratio of projected frontal height to chord length  $h$  plotted against angle of attack  $\alpha$  for the airfoils used herein. For the swept airfoils,  $h$  and  $s$  are referred to the free-stream direction.

Total collection efficiency and impingement limits are often presented in terms of  $K$  and  $\phi$ , where  $K$  indicates the inertia of the droplet and  $\phi$  represents the deviation of the droplet drag forces from Stokes' law, for correlating impingement characteristics. Reference 17 discusses and illustrates previously determined analytical airfoil impingement data in terms of a modified  $K$  parameter defined as  $K_0 = K(\lambda/\lambda_B)$ . The ratio  $\lambda/\lambda_B$  is a function of  $Re_0$  as shown in figure 6 (data from ref. 12). Plotting a dependent impingement parameter such as  $E_m$  or  $s_{\max}$  as a function of  $K_0$  yields a set of experimentally or analytically determined points that can be essentially represented

3689

by a single curve, independent of  $\phi$ . This curve is approximately the solution obtained using Stokes' law for sphere (droplet) drag. The extension or interpolation of experimental as well as analytical data points over a wide range of the pertinent impingement variables (droplet size, body size, speed, and altitude) is greatly facilitated by this  $K_0$  parameter, even though no complete theoretical proof of its significance or validity is available at this time.

The impingement parameters previously discussed are often presented in the literature in terms of clouds containing droplets all of the same size. Analytical calculations show that the presence of a droplet-size distribution does not alter the usefulness of the  $K_0$  parameter if it is evaluated with the following droplet sizes: (1) The use of volume-median droplet size to calculate a "weighted"  $K_0$  will reduce weighted total collection efficiency to data representable by a single curve; and (2) the use of maximum droplet size in calculating  $K_0$  will reduce limits of impingement to data representable by a single curve. Reasonable extension and interpolation of experimental  $\bar{E}_m$  and  $s_{max}$  data obtained with droplet-size distribution for conditions other than those studied are possible, therefore, with the  $K_{0,med}$  or  $K_{0,max}$  parameter, respectively.

Correlation of  $\beta$  (uniform droplet size) or  $\bar{\beta}$  (distribution of droplet sizes) with  $K_{0,med}$  was possible only if each value of  $\beta$  or  $\bar{\beta}$  used was obtained for the same numerical value of  $s'$ , where  $s'$  is the dimensionless surface distance measured from the  $s$  location of  $\beta$  or  $\bar{\beta}$  to the location of  $\beta_{max}$  or  $\bar{\beta}_{max}$ , respectively.

From the theoretical and experimental impingement results, it was determined that the surface location of  $\beta_{max}$  or  $\bar{\beta}_{max}$ , measured from the zero-chord point, denoted as  $s''$ , does not occur at the same  $s$  location for various  $K_{0,med}$  values except for symmetrical airfoils at zero angle of attack. Generally,  $s''$  occurs between the air stagnation point on the airfoil (max. pressure point) and the foremost point on the airfoil. The foremost point on the airfoil is where the airfoil surface is perpendicular to the free-stream-velocity direction. As the value of the modified inertia parameter  $K_{0,med}$  increases,  $s''$  moves toward the foremost point on the airfoil, because the droplet paths approach straight-line trajectories. As the value of  $K_{0,med}$  decreases,  $s''$  moves toward the maximum pressure point, because the droplet inertia is approaching that of air particles.

The following empirical method of analysis was adopted for correlating  $\bar{\beta}$  with  $K_{0,med}$ . From plots of the experimental data of  $\bar{\beta}$  against  $s$ , values of  $\bar{\beta}$  were selected at specified values of  $s'$ . Plotting  $\bar{\beta}$  as a function of  $K_{0,med}$  for various  $s'$  values yields points reasonably

3689

represented by a single curve. The relation of these  $\bar{\beta}$  values to their true surface location  $s$  is accomplished by a plot of  $s''$  as a function of  $K_{O,med}$  and the relation

$$s = s' + s'' \quad (5)$$

A negative sign herein denotes the airfoil upper-surface values; a positive sign denotes the airfoil lower surface.

## RESULTS

A complete tabulation of the local collection efficiency  $\bar{\beta}$ , the maximum extent of impingement on the airfoil surface  $s_{max}$ , and the total collection efficiency  $\bar{E}_m$  for each airfoil and impingement condition studied is listed in table I. The  $\bar{\beta}$  values are tabulated as a function of  $s$ , the surface distance from the zero-chord point on the airfoil divided by chord length. These  $\bar{\beta}$  data are calculated from paired values of  $\bar{W}_\beta$  and equation (2). Typical  $\bar{W}_\beta$  values as a function of  $s$  are shown in figure 7 for several repeat runs. The data in this figure show a repeatability of better than  $\pm 10$  percent.

In order to emphasize the significant trends and variables affecting the impingement characteristics of airfoils, this section of the report presents the experimental data in terms of (1) typical  $\bar{\beta}$  curves as a function of  $s$  and (2) dimensionless  $K_{O,med}$  and  $K_{O,max}$  parameters. Part (1) consists in a general evaluation of the effect on impingement characteristics of the basic airfoil geometry, including such items as airfoil angle of attack, camber, thickness ratio, airfoil shape, and sweep angle. Part (2) presents the effects on airfoil impingement characteristics of varying the droplet size, airspeed, and model size as expressed by a variation of the dimensionless  $K_{O,med}$  and  $K_{O,max}$  parameters.

### Effect of Airfoil Geometry on Impingement Characteristics

In order to illustrate the effect of airfoil geometry and attitude on typical values of local collection efficiency,  $\bar{\beta}$  is presented as a function of surface distance divided by chord length  $s$  (fig. 8). The data used in figure 8 were obtained from table I.

Angle of attack. - An increase in angle of attack for the same spray cloud conditions will increase the extent of impingement on the lower surface of an airfoil  $s_{l,max}$  and decrease the extent on the upper surface  $s_{u,max}$ . In figure 8(a) (Joukowski 0015 airfoil at angles of attack

of  $0^\circ$ ,  $4^\circ$ , and  $8^\circ$ ) the impingement limit on the lower surface increased from a value of  $s_{l,max}$  of 0.158 to 0.379 as the angle of attack was increased from  $0^\circ$  to  $8^\circ$ . Concurrently, on the upper surface  $s_{u,max}$  decreased from -0.158 to -0.058.

Generally, for a given  $s$  the local  $\bar{\beta}$  values on the lower surface increase while those on the upper surface decrease as the angle of attack is increased. The value of  $\bar{\beta}_{max}$  has a tendency (both from experimental and theoretical data) to decrease slightly (less than 10%) as the angle of attack is increased from  $0^\circ$  to  $8^\circ$ . As the angle of attack is increased, the  $\bar{\beta}_{max}$  value is located farther aft along the lower surface, as shown in figure 8(a). At  $8^\circ$  angle of attack  $\bar{\beta}_{max}$  occurs at  $s''$  of 0.012 as compared with  $s''$  of 0.005 and 0 at  $4^\circ$  and  $0^\circ$ , respectively. The shape of the local  $\bar{\beta}$  curve is symmetrical or nearly symmetrical (depending on whether the airfoil is symmetrical or is cambered, respectively) at zero angle of attack. As the angle of attack is increased, the  $\bar{\beta}$  curve has a steeper impingement gradient on the upper surface and a lesser gradient on the lower surface. For the airfoils, droplet sizes, and operating conditions used herein, the location of  $\bar{\beta}_{max}$  occurs between the air stagnation region and the foremost point of the airfoil.

The  $\bar{E}_m$  values for the 12- to 16-percent thick airfoils show no great change with an increase in angle of attack (table I) over the range of  $K_{O,med}$  values studied (0.0057 to 0.093). However, these airfoils with increasing angle of attack will have an increased total water catch per foot of span almost proportional to the increased projected frontal height  $h$  of the airfoil (as will be discussed later). The total collection efficiency for the NACA 65<sub>1</sub>-206 airfoil also does not vary appreciably for the limited range of angles of attack and  $K_{O,med}$  values studied ( $0^\circ$  to  $4.3^\circ$  and 0.0077 to 0.0167, respectively). According to theoretical data for a thin airfoil (ref. 11), however, the  $E_m$  for the NACA 65A-004 airfoil increased markedly between angles of attack of  $0^\circ$  and  $8^\circ$ , the  $E_m$  being 40 to 80 percent greater at  $8^\circ$  than at  $0^\circ$  for  $K_O$  values of 0.01 and 0.10, respectively. Therefore, the  $\bar{E}_m$  for the NACA 65<sub>1</sub>-206 may increase for angles greater than  $4^\circ$  in the range of  $0.01 < K_{O,med} < 0.10$  in a manner similar to that for the NACA 65A-004.

Airfoil thickness. - A change in airfoil thickness ratio (for the same airfoil series) has mixed effects. An increase in thickness ratio causes a decrease in  $\bar{\beta}_{max}$  as shown in figure 8(b) (NACA 65<sub>1</sub>-206 and 65<sub>1</sub>-212 airfoils both at  $0^\circ$  angle of attack). The value of  $\bar{\beta}_{max}$  for the thin 65<sub>1</sub>-206 airfoil is 27 percent greater than that for the thicker 65<sub>1</sub>-212 airfoil. Between the region of  $\bar{\beta}_{max}$  and the limits of impingement, local  $\bar{\beta}$  values for a thick airfoil are generally higher than those

of a thin one. In figure 8(b), the upper-surface limit of impingement  $s_{u,max}$  on the 12-percent-thick airfoil is -0.06, while that on the 6-percent-thick airfoil is -0.09. The lower-surface limit of impingement  $s_{l,max}$  is 0.03 for the thick airfoil compared with 0.02 for the thin airfoil. For the range of cloud properties, angle of attack, and airfoil series studied herein, the higher values of  $\bar{\beta}_{max}$  and the smaller  $h$  of the 65<sub>1</sub>-206 airfoil yielded a higher total collection efficiency than those of the 65<sub>1</sub>-212 airfoil. (See table I, eq. (4), and subsequent discussion.)

Airfoil shape. - The NACA 65<sub>2</sub>-015 and 63<sub>2</sub>-015 and the Joukowski 0015 airfoils are compared in the same cloud conditions and at 0° angle of attack in figure 8(c). These three airfoils are symmetrical and have a maximum thickness of 15 percent; they differ in the location of maximum thickness and leading-edge radius (see fig. 2). The Joukowski 0015 is the bluntest, with the maximum-thickness point at 25-percent chord; the 65<sub>2</sub>-015 is the sharpest, with the maximum-thickness point at 40-percent chord; and the 63<sub>2</sub>-015 airfoil is intermediate, with maximum thickness at 35-percent chord. The blunt Joukowski 0015 has a lower  $\bar{\beta}_{max}$  value but higher local  $\bar{\beta}$  values farther aft on the surface than the sharp, low-drag 65<sub>2</sub>-015 airfoil. The value of  $\bar{\beta}_{max}$  for the 65<sub>2</sub>-015 airfoil was about 20 percent greater than for the Joukowski 0015. The 63<sub>2</sub>-015 airfoil data show  $\bar{\beta}_{max}$  values between those obtained for the other two 15-percent-thick airfoils. In addition, the limit of impingement on the bluff airfoil is less than that on the sharp low-drag airfoil, as shown in figure 8(c).

The total collection efficiency of the blunt airfoil (Joukowski 0015) in the range of  $K_{O,med}$  covered herein (0.04 to 0.1) is 20 to 40 percent higher than that of the low-drag airfoil (65<sub>2</sub>-015) of the same thickness ratio (table I). In the determination of the  $\bar{E}_m$  values for these airfoils, the higher  $\bar{\beta}_{max}$  and greater total impingement area of the low-drag airfoil (fig. 8(c)) are insufficient to offset the generally higher  $\bar{\beta}$  values (except near  $\bar{\beta}_{max}$ ) of the blunt airfoils.

Airfoil camber. - The extent of impingement at 0° angle of attack may be greater on the upper surface than on the lower surface for a cambered airfoil (fig. 8(b)); however, this is not generally true for angles greater than 0°. For the NACA 65<sub>1</sub>-212 airfoil, the maximum impingement limit on the upper surface  $s_{u,max}$  is -0.06, whereas on the lower surface the impingement limit is 0.03. No direct comparison of the effect of airfoil camber on local or total collection efficiency can be made with the

data available, because the same airfoil series was not studied with and without camber. An interpolation, however, of the  $\bar{E}_m$  data for the cambered 65-series airfoils (65<sub>1</sub>-206, 65<sub>1</sub>-212, and 65<sub>2</sub>-216, the last airfoil having similar geometric shape to the other two, (fig. 1)) to a cambered 15-percent-thick airfoil can be made. Comparison of these interpolated values of  $\bar{E}_m$  with those of the uncambered 65<sub>2</sub>-015 airfoil indicates that the small camber involved has only a secondary effect on the total collection efficiency.

Airfoil sweepback. - Sweeping back an airfoil and keeping the same physical shape (yawing the airfoil) generally have only a small effect on impingement limits and local and total collection efficiencies. Comparing the data for the unswept and swept 65-series airfoils (table I) shows that the collection efficiencies and limits of impingement are a little less, in general, on the yawed or swept airfoils than on the unswept airfoils. A correlation of swept- and unswept-airfoil impingement data is presented later in the DISCUSSION.

#### Dimensionless Presentation of Data

The experimental impingement characteristics of airfoils  $\bar{\beta}$ ,  $\bar{E}_m$ , and  $s_{max}$  are conveniently presented as a function of the pertinent modified inertia parameter  $K_{O,med}$  or  $K_{O,max}$  for purposes of extrapolation and comparison in figures 9 to 12. Presentation of data in this form permits a ready evaluation of airfoil impingement characteristics in terms of droplet size, air temperature, altitude, component size, and airspeed.

Variation of  $\bar{\beta}$  with  $K_{O,med}$ . - In figure 9, average  $\bar{\beta}$  values at selected surface locations  $s'$  are shown as functions of  $K_{O,med}$  for all airfoils studied. These locations of  $\bar{\beta}$  are referenced to the location of  $\bar{\beta}_{max}$  as discussed previously and were obtained from the original curves of  $\bar{\beta}$  against  $s$ . It is apparent from the curves shown in figure 9 that the method of analysis for  $\bar{\beta}$  (outlined in the ANALYSIS) will produce data that can be essentially represented by a single curve for particular  $s'$  locations.

In the range of  $0.04 < K_{O,med} < 0.1$  (13-in.-chord airfoil data) the point value of  $\bar{\beta}_{max}$  could not be readily ascertained because of the width of the blotter punch used. Generally, the  $\bar{\beta}_{max}$  curve for the 13-inch-chord airfoils is estimated from the more reliable data in the range of  $0.001 < K_{O,med} < 0.01$  and from the shape of the  $\bar{\beta}$  curves aft of  $\bar{\beta}_{max}$  ( $s' = 0.01$ , etc.) for the values of  $K_{O,med}$  greater than 0.04.

The local collection efficiency  $\bar{\beta}$  increases with an increase in  $K_{O,med}$  as shown in figure 9. The order of magnitude of the increase in  $\bar{\beta}$  as  $K_{O,med}$  increases depends on the surface location and is a complex function of the airfoil angle of attack and shape. In the range of  $0.01 < K_{O,med} < 0.1$ , the  $\bar{\beta}$  values are believed accurate to  $\pm 10$  percent; but, for  $\bar{\beta}_{max}$  at  $K_{O,med}$  greater than 0.02, a  $\pm 25$ -percent accuracy is estimated.

The curves of figure 10 present  $s''$  (the surface location of  $\bar{\beta}_{max}$ ) as a function of  $K_{O,med}$ . Because of the width of the blotter punch used,  $s''$  could not be precisely established. Consequently,  $s''$  is represented in figure 10 by a dashed line.

Variation of  $s_{max}$  with  $K_{O,max}$ . - An increase in  $K_{O,max}$  will increase the extent of impingement on both surfaces of the airfoil as shown in figure 11. With increasing  $K_{O,max}$  there is a greater change in the lower-surface limit of impingement on a low-drag airfoil (NACA 65<sub>1</sub>-212) than on a blunt airfoil (Joukowski 0015). On the upper surface no marked trends with airfoil shape are apparent except at 0° angle of attack. As previously discussed (fig. 8(a)), an increase in angle of attack will increase the extent of impingement on the lower surface and decrease the extent on the upper surface for all airfoils over the entire range of  $K_{O,max}$  values.

Variation of  $\bar{E}_m$  with  $K_{O,med}$ . - The total collection efficiency of an airfoil  $\bar{E}_m$  increases as  $K_{O,med}$  increases (fig. 12). These data are plotted from table I for an angle of attack of 0°. In the range of  $K_{O,med} < 0.02$  the increase in  $\bar{E}_m$  with a decrease in the thickness ratio is readily apparent in figure 12 for airfoils of the same series and camber. For example, at 0° angle of attack and  $K_{O,med}$  of 0.01 the  $\bar{E}_m$  values for the NACA 65<sub>1</sub>-206, 65<sub>1</sub>-212, and 65,2-216 airfoils are 0.105, 0.06, and 0.05, respectively. These airfoils, although their numbering systems are somewhat different, are of the same series, differing primarily in thickness ratio and only to a minor degree in leading-edge radius and location of maximum-thickness point. These latter differences are considered of secondary significance in the evaluation of total collection efficiency. Reversals of this change in  $\bar{E}_m$  with thickness ratio may occur at high  $K_{O,med}$  values ( $K_{O,med} > 0.02$ ), especially as the thickness ratio approaches 6 or 4 percent.

3689

The preceding  $\bar{E}_m$  comparisons do not necessarily mean a similar comparison for total water caught on an airfoil. For a two-dimensional wing the total water catch per foot span  $\bar{W}_m$  is

$$\bar{W}_m = 0.329 U_0 w_t c h \bar{E}_m \quad (6)$$

Total catch is thus proportional to the product of  $\bar{E}_m$ , projected frontal height  $h$ , and chord length  $c$ . For example, at  $0^\circ$  angle of attack and  $K_{O,med}$  of 0.007, the NACA 65,2-216 airfoil has an  $\bar{E}_m$  value of 0.032 and a  $\bar{W}_m$  value proportional to  $0.16 \times 0.032 = 0.0051$  (values from figs. 5 and 12). In comparison, the NACA 65<sub>1</sub>-206 has a higher  $\bar{E}_m$  value of 0.085 but  $\bar{W}_m$  proportional to  $0.06 \times 0.085 = 0.0051$  is the same. A similar comparison at  $K_{O,med}$  of 0.013 makes  $\bar{W}_m$  proportional to 0.0109 and 0.0072 for the NACA 65,2-216 and 65<sub>1</sub>-206, respectively, although  $\bar{E}_m$  for the thicker airfoil is about 40 percent less than that for the thinner one.

The effect of angle of attack on  $\bar{E}_m$  for all the airfoils studied at one spray condition is presented in figure 13. These data were obtained at a free-stream velocity  $U_0$  of 152 knots and a volume-median droplet diameter  $d_{med}$  of 16.7 microns (air-water pressure ratio, 0.6) and are typical of the other spray cloud conditions. (Cross plots of these data, obtained from table I, yield curves of  $\bar{E}_m$  against  $K_{O,med}$  similar to those of fig. 12.) As previously discussed,  $\bar{E}_m$  for the airfoils and spray conditions studied does not vary appreciably with angle of attack.

Because the  $h$  difference among the airfoils studied lessen as angle of attack increases (fig. 5), values of total water catch per foot span  $\bar{W}_m$  (see eq. (6)) will depend largely on the values of  $\bar{E}_m$  for angles of attack greater than  $4^\circ$ .

### DISCUSSION

The following discussion is based on comparison of the experimental results with available theoretical trajectory data. In order to compare experimental impingement data with that calculated from trajectory data for the same body, the flow fields in both cases must be similar. The local velocity distributions obtained experimentally on several of the airfoils are shown in figure 14. Also shown in this figure are the theoretical values used to set up the flow field for the trajectory calculations of reference 2. In general, the experimental results agree well

3689

(especially near the leading edge) with the theoretical. The experimental velocity distributions are generally slightly high on both surfaces by an average of 5 percent. At angles of attack up to  $4^\circ$ , the local velocity data from the large-chord airfoils agrees well with those for the small-chord airfoils.

### Impingement Characteristics

The theoretical impingement characteristics for the Joukowski 0015 airfoil at angles of attack of  $0^\circ$  or  $4^\circ$  and the unswept NACA 65<sub>1</sub>-212 airfoil at an angle of attack of  $4^\circ$  can be obtained from the trajectory studies of references 5 and 2, respectively. These trajectory results, when "weighted" (as described in ref. 1) for the droplet-size distribution of the tunnel spray cloud, can be used for a comparison between the experimental results obtained herein and the theoretical results.

The modified inertia parameter  $K_{O,max}$  is the independent variable chosen as the basis for comparing the experimental limits of impingement  $s_{max}$  with the theoretical (fig. 15). For the Joukowski 0015 airfoil (fig. 15(a)) in the range of  $K_{O,max}$  from 0.01 to 0.1, good agreement of the experimental impingement limits on both upper and lower surfaces with those of theory is obtained for angles of attack of  $0^\circ$  and  $4^\circ$ . Fair agreement is obtained for  $K_{O,max}$  greater than 0.1. In this higher  $K_{O,max}$  range the visual and colorimetric determinations of the experimental impingement limit, particularly on the lower surface, are more difficult than for  $K_{O,max}$  less than 0.1 and may account for the lesser agreement with theoretical values when  $K_{O,max}$  is greater than 0.1. For the NACA 65<sub>1</sub>-212 airfoil at  $\alpha$  of  $4^\circ$  (fig. 15(b)) there is poor agreement on both upper and lower surfaces between experiment and theory, the theoretical limits being twice the experimental. Even on the upper surface, where at  $4^\circ$  angle of attack the experimental limit is well defined, large discrepancies occur. As yet there is no reasonable explanation for these differences.

The experimental local collection efficiencies  $\bar{\beta}$  as a function of  $s$  are in good agreement with those obtained from theory for the Joukowski 0015 airfoil at both  $0^\circ$  and  $4^\circ$  angles of attack (fig. 16). A similar comparison of  $\bar{\beta}$  attempted for the NACA 65<sub>1</sub>-212 airfoil at  $4^\circ$  angle of attack yielded very erratic results. The erratic nature of these data may be due in large part to the inconsistencies in the theoretical trajectory data. For a given impingement condition ( $Re_0$  and  $K$ ), total collection efficiency  $E_m$  obtained by the tangent trajectory data of

3689

reference 2 differs by more than 30 percent, for example, from  $\bar{E}_m$  determined from an integration of the local collection efficiency results of the same reference (see eq. (4) herein).

Theoretical and experimental values of total collection efficiency  $\bar{E}_m$  for the Joukowski 0015 at angles of attack of  $0^\circ$  and  $4^\circ$  and the NACA 65<sub>1</sub>-212 at an angle of attack of  $4^\circ$  are compared in figure 17. For the Joukowski 0015 (figs. 17(a) and (b)) good agreement ( $\pm 10\%$ ) between theory and experiment is obtained over the entire  $K_{0,med}$  range studied. The  $\bar{E}_m$  value computed theoretically for the NACA 65<sub>1</sub>-212 airfoil (fig. 17(c)) is 25 and 100 percent greater than that obtained experimentally for  $K_{0,med}$  values of 0.09 and 0.008, respectively, because of the aforementioned discrepancies in  $s_{max}$  and  $\bar{\beta}$ . Similar comparisons between experiment and theory for the NACA 65<sub>2</sub>-015 airfoil at  $\alpha$  of  $4^\circ$  (theoretical in ref. 5) show the theoretical values to be 10 to 20 percent higher than the experimental values in the  $K_{0,med}$  range tested.

The agreement between the theoretical and experimental evaluations of  $\bar{E}_m$ ,  $\bar{\beta}$ , and  $s_{max}$  is considered good for the Joukowski 0015 and satisfactory for the NACA 65<sub>2</sub>-015. No such agreement was obtained for the NACA 65<sub>1</sub>-212 airfoil, as previously discussed. These three airfoils are the only ones available for comparison of experimental and theoretical impingement values at this time.

#### Correlation of Effect of Airfoil Sweepback

The experimental impingement data substantiate the method of reference 14 for predicting the impingement on a swept airfoil from data obtained on an unswept airfoil where (1) the wing can be considered two-dimensional or has a high aspect ratio and (2) the airfoil section in a plane perpendicular to the leading edge of the swept airfoil is the same section as that of the unswept airfoil. The application of the method of reference 14 to the experimental impingement data presented herein is discussed in appendix C. Typical experimental values of local collection efficiency  $\bar{\beta}$  as a function of  $s$  for the  $35^\circ$  swept (NACA 65<sub>1</sub>-212 and 65<sub>1</sub>-206) airfoils are presented for angles of attack (referenced to free-stream velocity direction) of  $0^\circ$  and  $4.3^\circ$  in figures 18(a) and (b), respectively. The paired lines of figure 18 represent the  $\bar{\beta}$  values calculated from the unswept experimental data by the method of reference 14. Good agreement between calculated swept and experimental swept values of  $\bar{\beta}$  was obtained for the angles of attack and the airfoils studied. Similar good agreement was obtained for values of  $s_{max}$  and  $\bar{E}_m$ .

3689

## Application of Tunnel Impingement Data to Flight

Correlation of tunnel cloud characteristics with those reported in the literature for natural icing clouds. - Most of the reported data concerning droplet size and liquid-water content of natural icing clouds (refs. 18 to 20) have been obtained with rotating multicylinders that were permitted to ice for a known time interval. The rate of ice collection on various size cylinders is matched with the theoretical collection of these cylinders in a manner that determines the droplet size and liquid-water content of the cloud (ref. 1). Similarly, the dye catch on various size cylinders can be matched to the theoretical cylinder catch to evaluate the tunnel dyed-water spray cloud properties. Another method of using the theoretical cylinder data to determine cloud properties is that of reference 15, wherein the droplet sizes are determined from dye-tracer impingement rates on a single stationary cylinder or body for which theoretical trajectories are available. A modification of the method in reference 15 is the use of a 36.5-percent symmetrical Joukowski airfoil. Details of the dye-tracer droplet-size analysis using the 36.5-percent Joukowski are given in appendix B. The liquid-water content of the dyed-water spray cloud was obtained by an aspirating tube (ref. 15).

For droplets with diameters greater than 12 microns, the multicylinder matching, the single-cylinder solution, or the Joukowski airfoil solution each yield nearly the same absolute values of droplet size. Total liquid-water content, as measured by the aspirator, is nearly the same as that indicated by the multicylinder matching technique, and thus the volume-median droplet size is substantially the same for both the Joukowski-aspirator or multicylinder matching methods. The tunnel cloud properties and impingement data reported herein are based on the Joukowski-aspirator method. The difference or relation between the multicylinder matching and the Joukowski-aspirator evaluation of the tunnel spray cloud is illustrated in figure 19, which is a cross plot of the cloud properties as calibrated by the two techniques. The development of figure 19, a discussion of the relatively minor differences obtained, and the reasons for preferring the Joukowski-aspirator results over the multicylinder matching results are discussed in appendix B.

To apply the experimental data herein to flight conditions, a procedure is suggested and illustrated by a hypothetical problem, the conditions of which are as follows:

(1) Meteorological design conditions, based on multicylinder data:

Cloud volume-median droplet diameter, 15 microns  
Cloud total liquid-water content, 0.5 g/cu m  
Cloud droplet-size distribution, Langmuir "D"

(2) Section characteristics:

Airfoil section, NACA 65<sub>1</sub>-212  
 Airfoil chord length, 10 ft  
 Airfoil angle of attack, 4°

(3) Operating conditions:

True airspeed, 300 mph (261 knots)  
 Pressure altitude, 10,000 ft  
 Static air temperature, 12° F

For the example, it is desired to determine the local water collection rate at  $s_l$  of 0.02 and the lower surface limit of impingement  $s_{l,max}$ .

The meteorological conditions are converted from the multicylinder values to the Joukowski-aspirator values by using figure 19. The conversion results in a volume-median droplet size of 14.8 microns (Joukowski-aspirator value) and a water-content ratio of the aspirator to the multicylinder match of 1.12. This ratio yields an aspirator total liquid-water content  $w_t$  of 0.56 g/cu m. Values of  $K$  and  $Re_0$  are then calculated (0.03242 and 111.3, respectively). With this  $Re_0$ , a  $\lambda/\lambda_s$  ratio of 0.325 is obtained (fig. 6). The  $K_{O,med}$  calculated from  $K$  and  $\lambda/\lambda_s$  then amounts to 0.01054. In order to obtain  $\bar{\beta}$  at the desired lower-surface location,  $s'$  and  $s''$  must be obtained. The value of  $s''$  obtained from figure 10(f) and (g) at a  $K_{O,med}$  of 0.01054 is 0.0037. From equation (5),  $s'$  is then calculated to be 0.0163. The value of  $\bar{\beta}$  is now determined from figure 9(f) and (g) using the curves for 4° angle of attack and  $K_{O,med}$  of 0.01054; the result is a  $\bar{\beta}$  of 0.14. The local collection rate at  $s_l$  of 0.02 is calculated from equation (2), which gives a value of  $\bar{w}_\beta$  of 7.74 pounds per hour per square foot.

In order to determine the limit of impingement on the lower surface of the airfoil, the maximum droplet size in the cloud droplet distribution must be established. For the Langmuir "D" distribution as well as the tunnel spray distribution, an average ratio of  $d_{max}/d_{med}$  of 3.2 exists. Hence, the maximum droplet size for the example is 48 microns. A value of  $K_{O,max}$  is now determined in a manner similar to that used to obtain  $K_{O,med}$  (i.e., values of  $K_{max}$ ,  $Re_{O,max}$  and  $\lambda/\lambda_{s,max}$  are determined). The result of these calculations is a  $K_{O,max}$  value of 0.0692, from which a value of  $s_{l,max}$  of 0.12 is obtained by use of figures 11(f) and (g).

3689

Effect of droplet-size distribution on impingement characteristics. -

A natural icing cloud may contain a distribution of droplet sizes (perhaps distribution types "B" to "E" defined in ref. 12), or the droplets in a cloud may be all the same size ("A" distribution). Many current design specifications are based on this assumption of an "A" distribution. For large bodies, such as root sections of tapered wings or radomes (low  $K_{O,med}$  range), the wider droplet-size distributions will result in higher values of  $\bar{E}_m$  than will an "A" distribution. Therefore, icing-protection equipment designed for large bodies and an "A" droplet-size distribution may underestimate  $\bar{E}_m$  and prove inadequate for some icing conditions. On the other hand, in the high  $K_{O,med}$  range typical for tip sections of tapered wings, helicopter blades, and instruments, the assumption of an "A" distribution may overestimate  $\bar{E}_m$  slightly when compared with an assumption of a wider droplet-size distribution.

Limit of impingement is a function only of the maximum droplet size present in the distribution. Because typical distributions often contain droplets 2 to 3 times larger than the uniform size of the "A" distribution, the extent or limit of impingement will be markedly increased if a droplet-size distribution other than "A" is experienced. In addition, the  $\beta$  profile will be altered by different droplet-size distributions.

Therefore, a droplet-size distribution that occurs relatively frequently in nature should be considered in the design of all icing-protection equipment. According to references 18 to 20, typical size distributions in nature range from a Langmuir "C" to "E". As previously discussed, the tunnel distribution of droplet sizes approximates a Langmuir "D". Consequently, the droplet-size distribution inherent in the data reported herein is typical of that in many natural icing clouds, making these data suitable for design purposes.

#### CONCLUDING REMARKS

In an effort to obtain a general solution to the impingement characteristics of various airfoils, some investigators have suggested that correlation of impingement characteristics could be obtained if the body dimension used in the independent impingement parameters were based on airfoil thickness (ref. 21) or projected frontal height of the airfoil (ref. 22). In both of these references relatively good correlation was obtained for a limited number of airfoils at an angle of attack of  $4^\circ$ . Subsequent data obtained at other angles of attack, particularly  $0^\circ$ , tend to show that the correlation at  $4^\circ$  was fortuitous. Much of the available theoretical  $E_m$  data at  $0^\circ$  angle of attack is shown in figure 20(a) as a function of  $K_{O,F}$ , where  $K_{O,F}$  is based on the projected height of the

6889

CT-3 back

airfoil rather than the chord. (At  $0^\circ$  angle of attack the projected height is equal to the airfoil thickness.) It is apparent that at values of  $K_{O,F}$  greater than 0.2 a wide deviation in total collection efficiency occurs, and the thick airfoils (thickness ratios 15 to 36.5%) have a higher collection efficiency than the thin airfoils (thickness ratios 4 to 6%). Conversely, in the low ranges of  $K_{O,F}$  the opposite trend is noted.

A similar plot of data at a  $4^\circ$  angle of attack in figure 20(b) shows the same good correlation of data for the various airfoils as noted in reference 22. The apparent good agreement at the  $4^\circ$  angle of attack may be due to the fact that at  $\alpha$  of  $4^\circ$  compared with  $\alpha$  of  $0^\circ$  the projected frontal height of the thin airfoils more nearly approaches that of the thick airfoils (see fig. 5), thereby reducing the effect of the thickness ratio on impingement characteristics and parameters. The experimental data for collection efficiency show trends similar to figure 20 when plotted in the  $K_{O,F}$  form.

At present, there is no known parameter that accurately correlates all the available two-dimensional airfoil impingement data over realistic ranges of the independent variables.

#### SUMMARY OF RESULTS

The impingement characteristics of several airfoils obtained experimentally using a dye-tracer technique yield the following results:

1. In general, the data show that the local and total water catch and the limit of impingement of airfoils are primary functions of the modified inertia parameter (in which airspeed and droplet and body size are the most significant variables) and airfoil thickness ratio. In addition, the local water collection rate and the extent of impingement on the airfoil surfaces depend on the airfoil angle of attack. Secondary factors affecting airfoil impingement characteristics are airfoil shape (for a given thickness ratio), small camber, and sweep angle.

2. With an increase in the modified inertia parameter, the total and local collection efficiencies and the impingement limits also increase. For those airfoils of a comparable series operating at a typical flight value of the modified inertia parameter, a thickness ratio of 6 percent had total collection efficiencies of 1.7 and 2 times those of a 12- and 16-percent-thick airfoil, respectively. Airfoils with relatively blunt leading edges (Joukowski 0015) had higher total collection efficiencies than those with sharp leading edges (low-drag airfoils such as the NACA 65<sub>2</sub>-015), although the impingement limits for the sharper airfoils were greater than those for the blunt airfoils.

3. The experimentally determined local and total collection efficiencies and impingement limits for the Joukowski 0015 and NACA 65<sub>2</sub>-015 airfoils are in good agreement with the theoretical values. No such agreement is obtained for the NACA 65<sub>1</sub>-212 airfoil.

4. Over the range of conditions studied, the experimental data substantiate a previous method of predicting the impingement characteristics of swept airfoils (design section laid out perpendicular to the leading edge) from data for the unswept design section.

5. Because of the typical droplet-size distribution of the tunnel spray, and the correlation of data by means of the modified inertia parameter, the experimental results herein may be applied over a wide range of flight conditions.

APPENDIX B

DETERMINATION OF CLOUD DROPLET SIZE AND LIQUID-WATER

CONTENT FROM MEASURED IMPINGEMENT RATES ON BODIES

Cloud droplet size and liquid-water content can be obtained from measured impingement rates on a body for which theoretical trajectory data are known (ref. 15). Most of the published cloud characteristics have been obtained by collecting ice on various size cylinders and matching these data to theoretical collection rates (refs. 18 to 20). Similarly, the dye catch on various size cylinders can be matched with theory to evaluate the tunnel dyed-water spray cloud. A modification to the multicylinder technique is that of reference 15, wherein the impingement rates obtained by dye traces on one stationary cylinder suffice. A refinement to the method of reference 15 is the use of an airfoil (36.5% symmetrical Joukowski herein) instead of a cylinder. A discussion and comparison of these methods follow.

3689

Multicylinder Matching

To calibrate the tunnel dyed-water spray cloud by the multicylinder matching technique, seven nonrotating cylinders (diam. of 1/8, 1/4, 1/2, 1, 2, 4, and 6 in.) were covered with absorbent material and separately exposed in the tunnel cloud. The total water catch (as measured by the dye collected) per unit time, frontal area, and velocity ( $= \bar{E}_{m w_t}$ ) is plotted in figure 21 as a function of cylinder diameter including thickness of absorbent material. The log-log plot of figure 21 is the conventional presentation for analyzing multicylinder data (ref. 1). By the matching method described in reference 1, the tunnel data of figure 21 can be matched to a theoretical Langmuir "D" droplet-size distribution. As discussed in reference 1, there is usually considerable latitude in selecting the best theoretical fit to any multicylinder data. A Langmuir "D" distribution is selected for the tunnel data because it provides for the airfoils studied herein, the best over-all agreement of limits and rates of impingement with those calculated theoretically. This agreement was previously discussed and illustrated in figure 16, where experimental and theoretical impingement rates ( $\bar{\beta}$ ) on the Joukowski 0015 airfoil are compared. Matching the tunnel multicylinder data to a Langmuir "D" droplet-size distribution yields the following spray cloud characteristics:

CTI-4

Air-water pressure ratio	Volume-median droplet diameter, $d_{med}$ , microns	Liquid-water content, $w_t$ , g/cu m
0.5	21.2	0.54
.6	16.8	.43
.8	11.6	.25

**Single Cylinders or 36.5-Percent Joukowski Airfoils**

In reference 15 a method for determining droplet-size distribution is described in which the theoretical trajectory results for cylinders (ref. 1) are applied to experimental impingement obtained on cylinders with the dye-tracer technique. Reference 15 shows that the experimental pressure distribution about cylinders deviates considerably from theory; these surface pressure differences probably reflect unknown differences in the flow field ahead of cylinders and hence droplet trajectories about cylinders. In order to eliminate or reduce these unknown effects, a 36.5-percent-thick symmetrical Joukowski airfoil (coordinates listed in table II) has been selected herein for which the experimental pressure and thus velocity distributions are in good agreement with the theoretical values (shown in fig. 22). In addition, a bluff configuration like the 36.5-percent Joukowski lends itself to accurate determination of the point where a droplet impinges on the surface, a critical factor in evaluating experimentally as well as theoretically the pertinent impingement variables  $s_{max}$ ,  $\beta$ , and  $E_m$ . The 36.5-percent Joukowski was studied theoretically (unpublished trajectory data) and with the dye-tracer technique. For the 36.5-percent Joukowski experimental studies, airfoils of 5.47- and 16.32-inch chord were used. These chord sizes gave about the same leading-edge diameters as the 2- and 6-inch cylinders of reference 15 and thereby provided a dimensional similarity for comparing the results from the two types of bodies.

The experimental techniques and methods of determining droplet size from 36.5-percent Joukowski dye traces are identical to those detailed for cylinders in reference 15. In the Joukowski analysis, the surface distance from the zero-chord point is denoted as  $s$ , whereas in the cylinder analysis surface distance is given by the central angle  $\theta$ . Curves of  $s_{max}$  as a function of  $K$  and  $\phi$ , and  $\beta$  as a function of  $s_{max}$  and  $s$  are given for the 36.5-percent Joukowski airfoil in figures 23 and 24, respectively. These theoretical Joukowski results were obtained at the Lewis laboratory with the mechanical analog described in reference 23. Figures 23 and 24 for the 36.5-percent Joukowski airfoil are comparable to figures 15 and 16, respectively, of reference 15 and are used with the experimental results (unpublished) in the same manner.

3689

From such a procedure dimensional plots of droplet diameter as a function of cumulative liquid-water content can be obtained.

Comparison of Multicylinder, Single-Cylinder,  
and 36.5-Percent Joukowski Airfoil Solutions

A curve of droplet diameter against cumulative liquid-water content based on data obtained from the Joukowski airfoils for each of the three tunnel spray conditions used herein is shown in figure 25(a). In addition to the 36.5-percent Joukowski solution of droplet sizes, the multicylinder matching the Langmuir "D" solution obtained from figure 21 and the single-cylinder solutions of reference 15 are presented for comparison. The average solution from each of the three methods is represented by the faired curves of figure 25. These averages are adjusted to common liquid-water contents. This adjustment is necessary for comparison on a dimensional basis, because data for the three methods of resolution were not obtained from the identical array (number and spacing) of spray nozzles. It is apparent from the curves that the solutions are in reasonable agreement.

Further comparisons of the methods of determining droplet size are presented in figure 25(b). For convenience, the cylinder size results of reference 15 are reproduced together with the 36.5-percent Joukowski results for the two chord sizes studied. The 36.5-percent Joukowski airfoil solutions in figure 25(b) are considered first, and each chord size gives a slightly different droplet-size distribution. However, the consistent body-size trend for droplet diameters less than 16 microns noted in the cylinder data (ref. 15) no longer exists. In addition, the over-all spread in droplet size at a particular liquid-water content value is markedly reduced for droplet diameters greater than 16 microns. Ideally, different body sizes exposed to the same cloud should indicate the same droplet-size distribution. However, as discussed in reference 15, the consistent body-size trend for cylinders may be the result of nonideal flow about cylinders or unaccounted-for droplet drag increments due to droplet acceleration. Furthermore, difficulties encountered in calculating accurately the theoretical trajectories in the range of low  $K$  values (less than about 0.7) also may contribute to the cylinder size trend when the theoretical data are applied in the analysis of the experimental data. The air flow about the 36.5-percent Joukowski is nearly ideal, as previously discussed and illustrated in figure 22. This improved air flow and an increased accuracy of the theoretical trajectory data in the low  $K$  range for the 36.5-percent Joukowski airfoil evidently yield results nearer the ideal than those from cylinders, as shown in figure 25(b).

3689

CT-4 back

In summary, the 36.5-percent Joukowski solution of droplet size is preferred over a single or multicylinder solution because (1) the consistent body-size trend noted for cylinders is absent, and (2) the body-size spread throughout the droplet-size range is reduced. An aspirating tube (ref. 15) is the preferred instrument in measuring total liquid-water content, because its collection efficiency is adjusted to be 100 percent whereas the calculated efficiency for cylinders may be inaccurate in the low  $K$  range.

Joukowski-aspirator values of volume-median droplet size and liquid-water content comparable to those previously tabulated in this appendix for the multicylinder matching method are as follows:

Air-water pressure ratio	Volume-median droplet diameter, $d_{med}$ , microns	Liquid-water content, $w_t$ , g/cu m
0.5	18.6	0.60
.6	16.7	.47
.8	11.5	.30

A dimensionless droplet-size distribution as obtained by the Joukowski-aspirator method is discussed in the text and is presented in figure 3.

Although the Joukowski-aspirator method of determining droplet size and liquid-water content of the dyed spray cloud is used to present the airfoil impingement characteristics herein, most of the published data on cloud characteristics have been obtained by the multicylinder matching method. The relation between the two methods for the range of conditions studied is obtained by a cross plot of the droplet sizes and liquid-water contents obtained by the two techniques. This cross plot, consisting of the data tabulated in this appendix, is shown as figure 19, and its use discussed in the text.

#### Values of Total Liquid-Water Content Reported in Reference 15

The aspirator values of total liquid-water content as reported in reference 15 are in error because of an undetected recirculation of the dyed spray cloud. The error was incurred by operating the aspirator for a longer time than required for the air and dyed droplets in the tunnel to recirculate. This phenomenon resulted in aspirator values of total liquid-water content higher than the true value by the amount of recirculated dye. Recent studies have evaluated the effect of recirculation for all spray conditions, and the effect is only significant for values of total liquid-water content (and thus by definition volume-median droplet size). The corrections to liquid-water content and

3689

volume-median droplet size (the latter based on analysis of cylinder impingement data) given in reference 15 are tabulated as follows:

Air-water pressure ratio	Liquid-water content, $w_t$ , g/cu m		Volume-median droplet diameter, $d_{med}$ , microns	
	Reference 15	Reference 15 corrected	Reference 15	Reference 15 corrected
0.5	0.70	0.46	14.8	20.4
.6	.58	.37	12.0	16.6
.8	.43	.22	7.6	12.0

The cylinder impingement, techniques, and method of solution for droplet size are unchanged from those reported in reference 15. The cylinders were exposed to the dyed spray cloud and then withdrawn from the tunnel before the circuit time of the tunnel air was complete (approx. 14 sec at an airspeed in the test section of 152 knots). The recirculated spray cloud for all conditions studied contains droplets less than 5 microns in diameter with recirculation dying out completely in a few minutes. Even for the 13-inch-chord airfoils, these small droplets impinge in a very narrow band (less than 1/16 in.) at or near the leading edge. The effect of these recirculated droplets on all the airfoil impingement characteristics is considered negligible. Total liquid-water contents for the airfoils studied herein are measured with aspirator exposure times significantly less than the tunnel air circuit time.

3689

APPENDIX C

PREDICTION OF IMPINGEMENT ON SWEEP AIRFOIL  
 FROM RESULTS OBTAINED ON UNSWEEP AIRFOIL

Reference 14 presents a method for predicting the impingement on a swept wing from impingement data for an unswept airfoil section if the unswept airfoil section is in the plane perpendicular to the leading edge of the swept wing. Limit of impingement and local and total collection efficiency are first determined with respect to flow conditions in the normal plane of the swept wing and then by geometry into the free-stream plane.

The 35° swept NACA 65<sub>1</sub>-212 and 65<sub>1</sub>-206 models studied herein were layed out with the sections in a plane perpendicular to the leading edge. Data from these swept airfoils are therefore directly comparable with the data from the unswept airfoils modified by the method of reference 14. Application of the unswept data as discussed in reference 14 to the swept airfoils is as follows (the NACA 65<sub>1</sub>-212 airfoil is used as an example):

(1) For a particular value of  $K_{O,med}$ ,  $\bar{\beta}$  is obtained from figure 9(f) and (g) for several values of  $s'$  and angles of attack  $\alpha$ . By using figure 10 and equation (5),  $s'$  is converted to  $s$ . The  $K_{O,med}$  value used to enter figure 9(f) and (g) is smaller than that at which the data were obtained. The value of  $K_{O,med}$  is smaller because  $U_{O,x}$  is replaced by  $U_{O,n}$ , where  $U_{O,n} = U_{O,x} \cos \gamma$ ; this has a greater effect on  $K_{O,med}$  than the accompanying increase in  $\lambda/\lambda_s$  (a function of  $Re_0$  and also decreased by  $\cos \gamma$ ).

(2) The values of  $\bar{\beta}$  obtained from step (1) are plotted against angle of attack  $\alpha$  for constant values of  $s$ .

(3) The  $\bar{\beta}$  values are read from the plot described in step (2) at  $\alpha_n = \alpha/\cos \gamma$  for several values of  $s$ . The  $\bar{\beta}$  values thus obtained ( $\bar{\beta}_n$ ) are in terms of a plane perpendicular to the leading edge of the swept airfoil.

(4) The  $\bar{\beta}_n$  values from step (3) are multiplied by  $\cos \gamma$  to obtain  $\bar{\beta}_x$  values on the swept airfoil. Therefore,  $\bar{\beta}_x$  is in terms of a plane perpendicular to the free-stream-velocity direction. This latter definition of  $\bar{\beta}$  (actually  $\bar{\beta}_x$ ) is identical to the conventional one for unswept bodies.

(5) The  $s$  (actually  $s_n$ ) values of steps (1) to (3) are in terms of a plane perpendicular to the leading edge of the swept airfoil. These  $s_n$  values are converted to corresponding  $s_x$  values from the geometry of the "stretched" airfoil (the NACA 65<sub>1</sub>-212 section in plane perpendicular to leading edge stretched to a thinner section in the free-stream plane). For the NACA 65<sub>1</sub>-212 and 65<sub>1</sub>-206, the difference between  $s_n$  and  $s_x$  is of secondary importance.

Unswept experimental  $\bar{\beta}$  values modified by the preceding procedure are compared with experimental swept data in figure 18, and discussed in the text.

FRAC

3689,

Figure 1. - Typical installation of airfoil (NACA 65<sub>1</sub>-212) with blotter attached, in 6- by 9-foot test section of icing tunnel.

(a) and (b)

(c)

(d)

(e)

<sup>1</sup>Designated section is in plane perpendicular to leading edge; leading edge is swept 35°.

Figure 2. - Airfoil sections studied with dye-tracer technique. Sections laid out in free-stream direction.

Figure 3. - Dimensionless droplet-size distribution of tunnel spray obtained on 36.5-percent Joukowski airfoil (see appendix B).

(a)  $\frac{1}{8}$  - By  $1\frac{1}{2}$ -inch segments.

(b)  $\frac{1}{16}$  - By 1-inch segments.

C-42776

Figure 4. - Typical blotter records from airfoils after exposure to dye cloud with punched segments removed for colorimetric analysis.

3689

CT-6 back

Figure 5. - Effect of angle of attack on ratio of projected height to chord length of various airfoils. (Reference is free-stream-velocity direction.)

Figure 6. - Droplet range ratio as function of droplet Reynolds number (data from ref. 12).

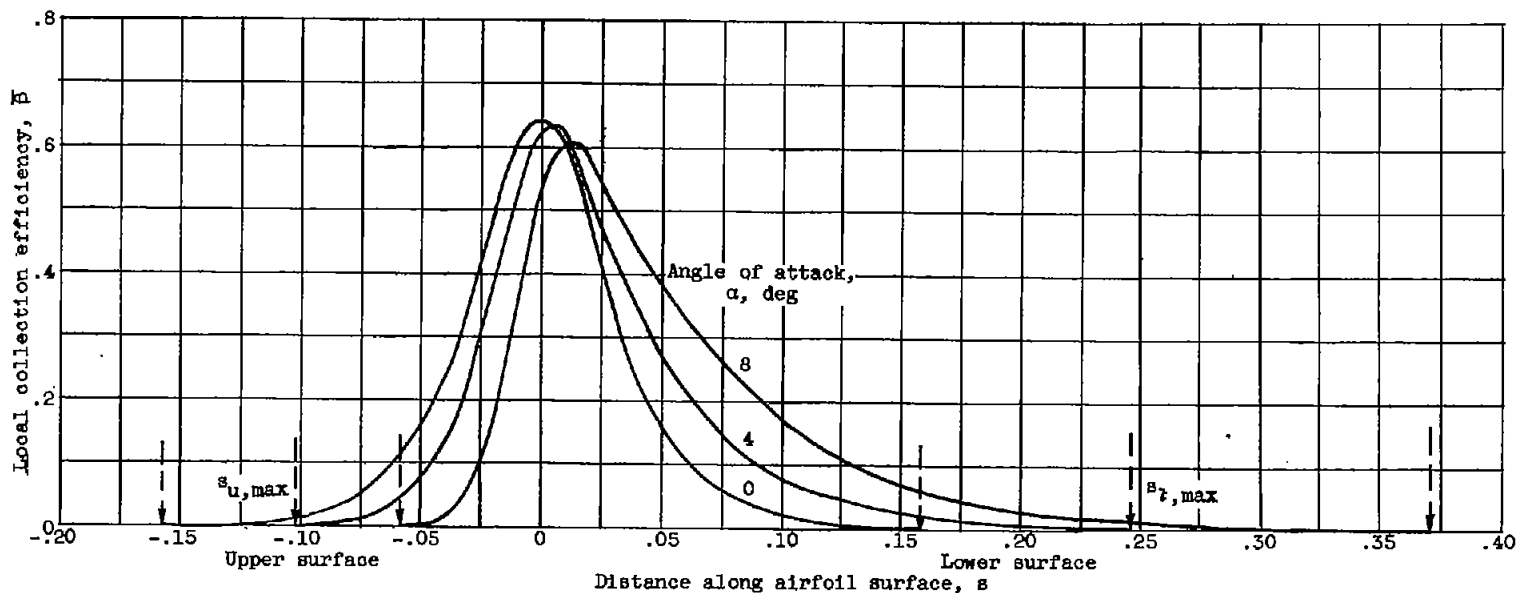

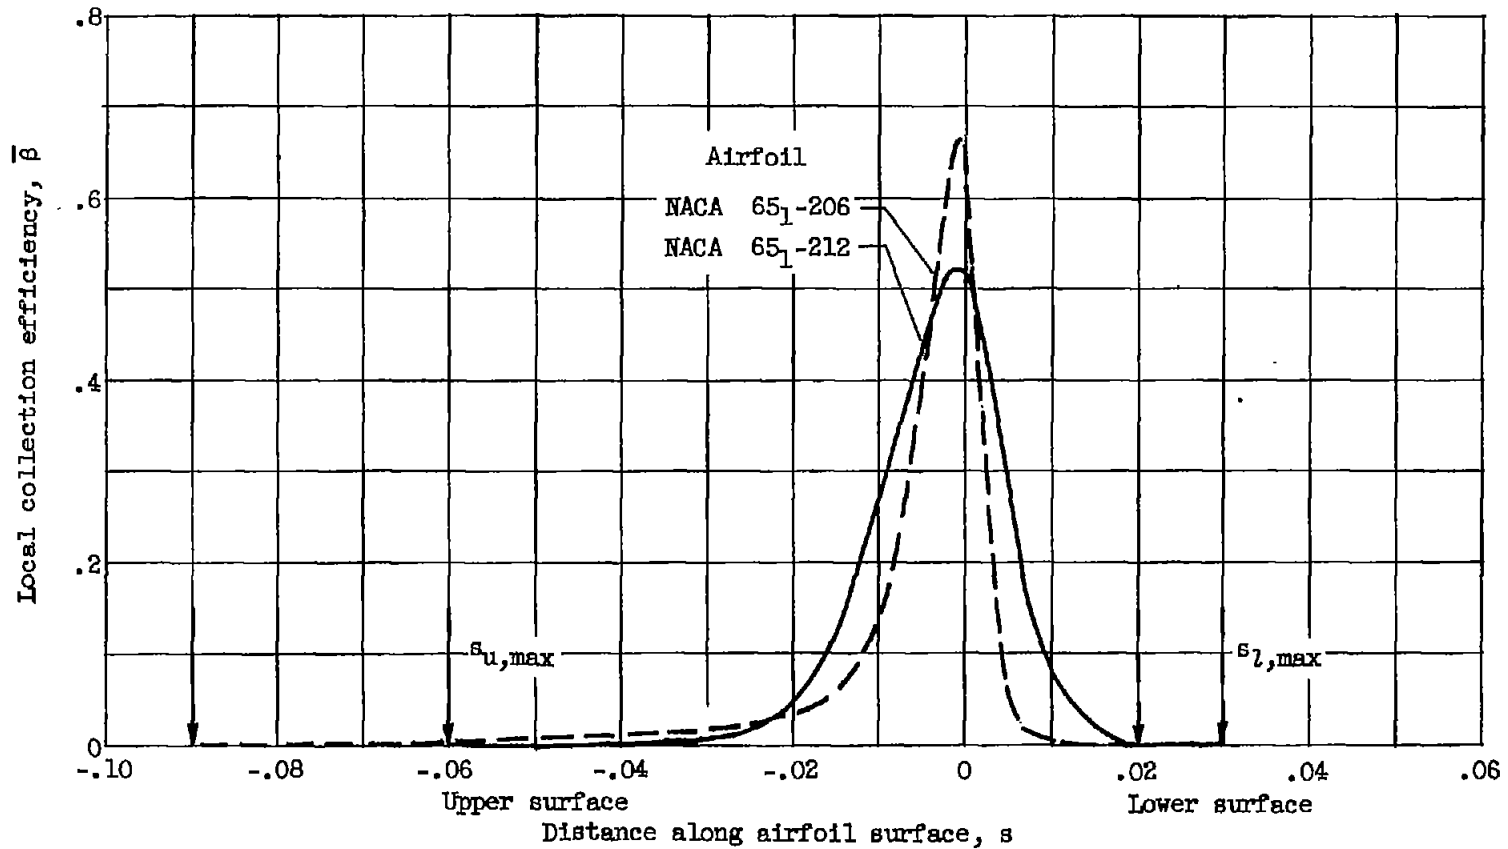

Figure 7. - Typical water impingement rates on NACA 65<sub>1</sub>-212 airfoil. Airspeed, 152 knots; volume-median droplet diameter, 16.7 microns; angle of attack, 4°.

(a) Angle of attack effect. Joukowski 0015 airfoil; 13-inch chord.

Figure 8. - Effect of airfoil geometry and angle of attack on local collection efficiency. Airspeed, 152 knots; volume-median droplet diameter, 16.7 microns.

(b) Thickness effect. Angle of attack,  $0^\circ$ ; 72-inch chord.

Figure 8. - Continued. Effect of airfoil geometry and angle of attack on local collection efficiency. Airspeed, 152 knots; volume-median droplet diameter, 16.7 microns.

(c) Shape effect. Angle of attack,  $0^\circ$ ; 13-inch chord.

Figure 8. - Concluded. Effect of airfoil geometry and angle of attack on local collection efficiency. Airspeed, 152 knots; volume-median droplet diameter, 16.7 microns.

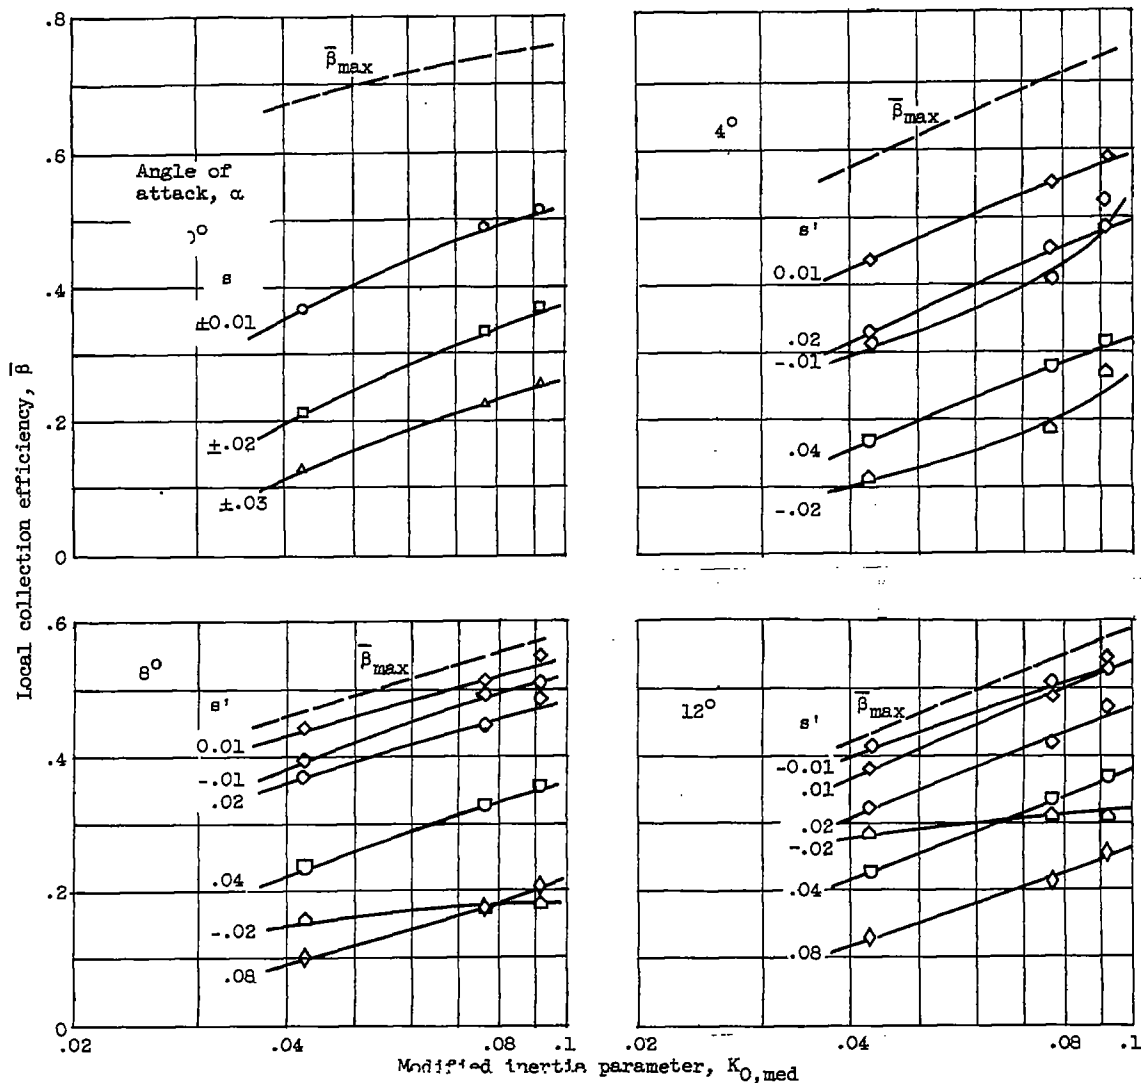

3689

CIT-7

(a) and (b) Joukowski 0015 airfoils. Chord, 13 and 96 inches.

Figure 9. - Local collection efficiency of airfoils as function of modified inertia parameter and surface location.

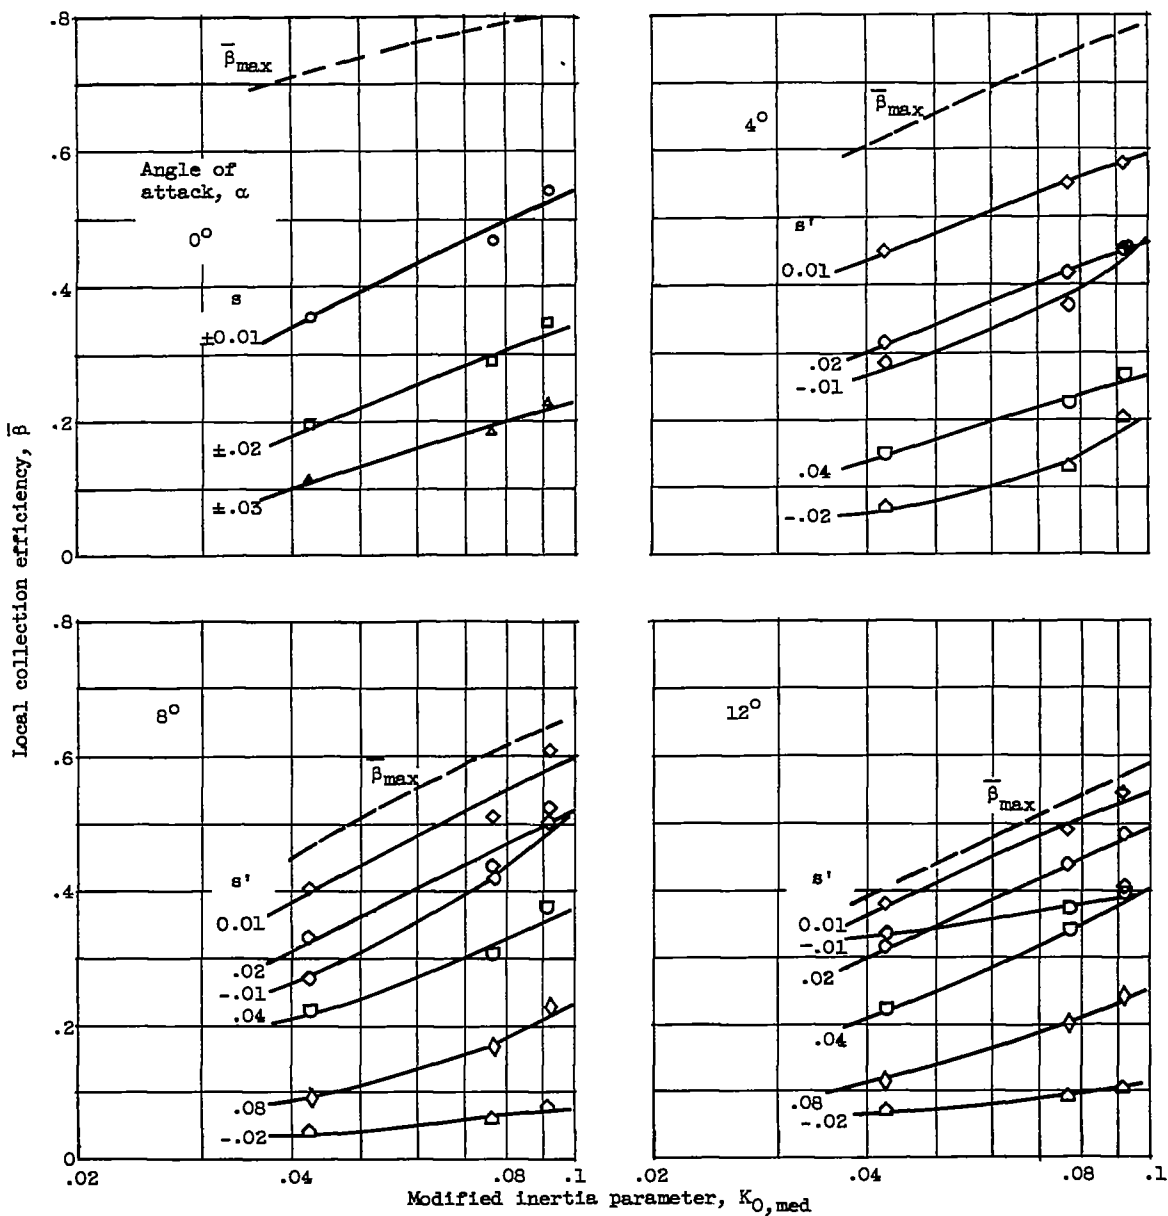

(c) NACA 63<sub>2</sub>-015 airfoil. Chord, 13 inches.

Figure 9. - Continued. Local collection efficiency of airfoils as function of modified inertia parameter and surface location.
